#### Abstract

$d$-dimensional efficient range-summability ( $d \mathrm{D}$-ERS) of a long list of random variables (RVs) is a fundamental algorithmic problem that has applications to two important families of database problems, namely, fast approximate wavelet tracking (FAWT) on data streams and approximately answering range-sum queries over a data cube. In this work, we propose a novel solution framework to $d$ D-ERS for $d>1$ on RVs that have Gaussian or Poisson distribution. Our solutions are the first ones that compute any rectangular range-sum of the RVs in polylogarithmic time. Furthermore, we develop a novel $k$-wise independence theory that allows our $d$ D-ERS solutions to have both high computational efficiencies and strong provable independence guarantees. Finally, we generalize existing DST-based solutions for 1D-ERS to 2D, and characterize a sufficient and likely necessary condition on the target distribution for this generalization to be feasible.

## 1 Introduction

Efficient range-summability (ERS) of ideally i.i.d. random variables (RVs) is a fundamental algorithmic problem that has been studied for nearly two decades [4, 20, 5, 13]. This problem has so far been defined only in one dimension (1D) as follows. Let $X_{0}, X_{1}, \cdots, X_{\Delta-1}$ be a list of ideally (mutually) independent underlying $R V s$ each of which has the same target distribution $X$. Here, the (index) universe size $\Delta$ is typically a large number (say $\Delta=2^{64}$ ). Given a range $[l, u) \triangleq\{l, l+1, \cdots, u-1\}$ that lies in $[0, \Delta)$, we need to compute $S[l, u) \triangleq \sum_{i=l}^{u-1} X_{i}$, the sum of the underlying RVs $X_{l}, X_{l+1}, \cdots, X_{u-1}$ in the range. A straightforward but naive solution to this problem is to generate underlying RVs $X_{l}, X_{l+1}, \cdots, X_{u-1}$ individually and then add them up. This solution, however, has a time complexity of $O(\Delta)$ when $u-l$ is $O(\Delta)$, which is inefficient computationally when $\Delta$ is large. In contrast, an acceptable solution [4, 20, 5, 13] should be able to do so with only $O($ polylog $(\Delta))$ time complexity.

In this work, we formulate the ERS problem in $d$ dimensions, which we denote as $d \mathrm{D}-\mathrm{ERS}$, and propose the first-ever solutions to $d \mathrm{D}-E R S$ for $d>1$. The $d \mathrm{D}$-ERS problem is defined on a $d$-dimensional $(d \mathrm{D})$ universe $[0, \Delta)^{d}$ that contains $\Delta^{d}$ integral points. Each $d \mathrm{D}$ point $\overrightarrow{\mathbf{i}}=\left(i_{1}, i_{2}, \cdots, i_{d}\right)^{T} \in[0, \Delta)^{d}$ is associated with a random variable $X_{\overrightarrow{\mathbf{i}}}$ indexed by it, and these $\Delta^{d}$ underlying RVs are ideally independent and every such RV has the same target distribution

$X$. Here, for ease of presentation, we assume $\Delta$ is the same on each dimension and is a power of 2 , but our solutions can work without these two assumptions. Let $\overrightarrow{\mathbf{l}}=\left(l_{1}, l_{2}, \cdots, l_{d}\right)^{T}$ and $\overrightarrow{\mathbf{u}}=\left(u_{1}, u_{2}, \cdots, u_{d}\right)^{T}$ be two $d \mathrm{D}$ points in $[0, \Delta)^{d}$ such that $l_{j}<u_{j}$ for each dimension $j=1,2, \cdots, d$. We define $[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}})$ as the $d \mathrm{D}$ rectangular range "cornered" by these two points in the sense $[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}}) \triangleq\left[l_{1}, u_{1}\right) \times\left[l_{2}, u_{2}\right) \times \cdots \times\left[l_{d}, u_{d}\right)$, where $\times$ is the Cartesian product. The $d \mathrm{D}$-ERS problem is that, given any $d \mathrm{D}$ range $[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}})$, we need to compute $S[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}}) \triangleq \sum_{\overrightarrow{\mathbf{i}} \in[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}})} X_{\overrightarrow{\mathbf{i}}}$, the sum of the underlying RVs in this $d \mathrm{D}$ range, in $O(\operatorname{polylog}(\Delta))$ time. Unless otherwise stated, the vectors that appear in the sequel are assumed to be column vectors. We write them in boldface and with a rightward arrow on the top like in " $\vec{x}$ ".

Several 1D-ERS solutions, to be described in Subsection 1.1 have been proposed as an essential building block for efficient solutions to several database problems. In two such database problems, their 1D solutions, both proposed in [6], can be readily generalized to $d \mathrm{D}$ if their underlying 1D-ERS solutions can be generalized to $d \mathrm{D}$. In fact, in [15], authors stated explicitly that the only missing component for their solutions of the 1D database problems to be generalized to 2D was an efficient 2D-ERS solution where $X$ is the Rademacher distribution $(\operatorname{Pr}[X=1]=\operatorname{Pr}[X=0]=0.5$, aka. single-step random walk). However, until this paper, no solution to any $d \mathrm{D}$-ERS problem for $d>1$ has been proposed.

### 1.1 Related Work on the One-Dimensional (1D) ERS Problem

There are in general two families of solutions to the ERS problem in 1D, following two different approaches. All existing solutions have the same asymptotic time complexity of $O(\log \Delta)$. The first approach is based on error correction codes (ECC). Solutions taking this approach include BCH3 [20], EH3 [4], and RM7 [1]. This approach has two drawbacks. First, it works only when the target distribution $X$ is Rademacher. Second, although it guarantees 3-wise (in the case of BCH 3 and EH 3 ) or 7 -wise (in the case of RM 7 ) independence among the underlying RVs, almost all empirical independence beyond that is destroyed.

The second approach is based on a data structure called dyadic simulation tree (DST) that we will describe in Subsection 2.1. The DST-based approach was first briefly mentioned in [5] and later fully developed in [13]. The DST-based approach is better than the ECC-based approach in that it supports a wider range of target distributions including Gaussian, Cauchy, Rademacher [13] and Poisson (to be shown in Subsection 4.5), and provides stronger and more flexible independence guarantees at lower computational costs, as will be elaborated in Section 3

### 1.2 Our dD-ERS solutions

In this section, we introduce our $d \mathrm{D}$-ERS solutions. All our solutions generalize the DSTbased approach and have a time complexity of $O\left(\log ^{d} \Delta\right)$. Our first solution is for the $d \mathrm{D}-$ ERS problem where the target distribution $X$ is standard Gaussian. We refer to this problem as $d \mathrm{D}$ Gaussian-ERS.

Our $d$ D Gaussian-ERS solution, based on the Haar wavelet transform (HWT), can be summarized as follows. Let $\overrightarrow{\mathrm{x}}$ denote the $\Delta^{d}$ underlying standard Gaussian RVs, $X_{\overrightarrow{\mathrm{i}}}$ for $\overrightarrow{\mathbf{i}} \in[0, \Delta)^{d}$, arranged (in dictionary order of $\overrightarrow{\mathbf{i}}$ ) into a $\Delta^{d}$-dimensional vector. Then, after the $d$ D-HWT is performed on $\overrightarrow{\mathbf{x}}$, we obtain another $\Delta^{d}$-dimensional vector $\overrightarrow{\mathbf{w}}$ whose scalars are the HWT coefficients of $\overrightarrow{\mathbf{x}}$. Our solution builds on the following two observations. The first observation is that scalars in $\overrightarrow{\mathbf{x}}$ are i.i.d. standard Gaussian RVs if and only if scalars in $\overrightarrow{\mathbf{w}}$ are ( $c f$. Theorem 2). The second observation is that any $d \mathrm{D}$ range-sum of ( $X_{\overrightarrow{\mathbf{i}}}$ )'s can be expressed as the weighted sum of $O\left(\log ^{d} \Delta\right)$ scalars in $\overrightarrow{\mathbf{w}}(c f$. Lemma 10). Our solution is
simply to generate only these $O\left(\log ^{d} \Delta\right)$ scalars in $\overrightarrow{\mathbf{w}}$ and compute this weighted sum, and hence has a time complexity of $O\left(\log ^{d} \Delta\right)$. Note this HWT-based solution does not work for any other target distribution in general, since the first observation is true only when the target distribution is Gaussian.

In this solution, to provably guarantee that all the $\Delta^{d}$ underlying RVs ( $X_{\overrightarrow{\mathbf{i}}}$ )'s are independent, in theory we need to make an idealized assumption that we can map every index $\alpha \in\left[0, \Delta^{d}\right.$ ) to a fresh RV $W_{\alpha}$ (the $\alpha^{t h}$ scalar in $\overrightarrow{\mathbf{w}}$ ) independently of other RVs using a truly random hash function [14]. In practice, we can instantiate our solution to achieve three different levels of independence guarantees using three different types of more practically implementable hash functions, respectively. One such instantiation, called the $k$-wise independence scheme and to be elaborated in Section 3 is another major contribution of this work. For any $k>1$, the $k$-wise independence scheme can be configured, by employing $O\left(\log ^{d} \Delta\right)$ $k$-wise independent hash functions to do this mapping (from $\alpha$ to $W_{\alpha}$ ), to guarantee that the underlying Gaussian RVs are $k$-wise independent. This scheme makes our Gaussian-ERS solution very practically useful for two reasons. First, such a $k$-wise independent hash function requires a seed of only $O(\log \Delta)$ bits in length and has only $O(k)$ computational complexity per hashing operation [2]. Second, most applications of ERS only require the underlying RVs to be 4 -wise independent [6, 15]. We will describe two such applications in Section 5

Our Gaussian-ERS solution generalizes the DST-based approach to higher dimensions because, in 1D, a DST is mathematically equivalent to an HWT, as will be shown in Subsection 2.1. Since, as mentioned earlier, there are DST-based ERS solutions for target distributions other than Gaussian in 1D, one may naturally wonder whether the DST-based approach can be generalized to higher dimensions in general. We find, however, the answer to this question is likely negative. In particular, we have identified a sufficient condition that, if satisfied by the target distribution $X$, guarantees that the corresponding DST-based solution for 1D can be generalized to $d \mathrm{D}$. The bad news is that so far we have found only two "nice" distributions, namely Gaussian and Poisson, that satisfy this sufficient condition, and that we have strong evidence that this condition is likely necessary. Interestingly, for all such "nice" distributions (including those we may discover in the future), this generalization process (from 1D to $d \mathrm{D}$ ) follows a universal algorithmic framework that we will describe in Subsection 4.4

## 2 An HWT-Based Solution to dD Gaussian-ERS

In this section, we describe our HWT-based $d$-dimensional ( $d \mathrm{D}$ ) Gaussian-ERS solution that can compute any $d \mathrm{D}$ range-sum in $O\left(\log ^{d} \Delta\right)$ time.

### 2.1 A Brief Introduction to Dyadic Simulation Tree

In this section, we briefly introduce the concept of the dyadic simulation tree (DST), which as mentioned earlier was proposed in [13] as a general solution approach to the one-dimensional (1D) ERS problems for arbitrary target distributions. The sole purpose of this introduction is to show that, when the target distribution is Gaussian, a DST is mathematically equivalent to a Haar wavelet transform (HWT) in the 1D case. We will also show that this equivalence carries over to higher dimensions. Note that this equivalence does not apply to any target distribution other than Gaussian, and hence the HWT representation cannot replace the role of DST in general.

Figure 1 Illustrations of a general DST and a Gaussian-DST with $\Delta=4$.
We say that $[l, u)$ is a 1 D dyadic range if there exist integers $j \geq 0$ and $m \geq 0$ such that $l=j \cdot 2^{m}$ and $u=(j+1) \cdot 2^{m}$. We call the sum on a dyadic range a dyadic range-sum. Note that any underlying RV $X_{i}$ is a dyadic range-sum (on the dyadic range $[i, i+1$ )). Let each underlying RV $X_{i}$ have standard Gaussian distribution $\mathcal{N}(0,1)$. In the following, we focus on how to compute a dyadic range-sum, since any (general) range can be "pieced together" using at most $2 \log _{2} \Delta$ dyadic ranges [20]. We illustrate the process of computing dyadic range-sums using a "small universe" example (with $\Delta=4$ ) shown in Figure 1a. To begin with, the total sum of the universe $S[0,4)$ sitting at the root of the tree is generated directly from its distribution $\mathcal{N}(0,4)$. Then, $S[0,4)$ is split into two children, the half-range-sums $S[0,2)$ and $S[2,4)$, such that RVs $S[0,2)$ and $S[2,4)$ sum up to $S[0,4$ ), are (mutually) independent, and each has distribution $\mathcal{N}(0,2)$. This is done by generating the RVs $S[0,2)$ and $S[2,4)$ from a conditional (upon $S[0,4)$ ) distribution that will be specified shortly. Afterwards, $S[0,2)$ is split in a similar way into two i.i.d. underlying RVs $X_{0}$ and $X_{1}$, and so is $S\left[2,4\right.$ ) (into $X_{2}$ and $X_{3}$ ). As shown in Figure 1a, the four underlying RVs are the leaves of the DST.

We now specify the aforementioned conditional distribution used for each split. Suppose the range-sum to split consists of $2 n$ underlying RVs, and that its value is equal to $z$. The lower half-range-sum $S_{l}$ (the left child in Figure 1a) is generated from the following conditional pdf (or pmf):

$$
\begin{equation*}
f(x \mid z)=\phi_{n}(x) \phi_{n}(z-x) / \phi_{2 n}(z) \tag{1}
\end{equation*}
$$

where $\phi_{n}(\cdot)$ is the pdf (or pmf) of $X^{* n}$, the $n^{t h}$ convolution power of the target distribution, and $\phi_{2 n}(\cdot)$ the pdf (or pmf) of $X^{* 2 n}$. Then, the upper half-range-sum (the right child) is defined as $S_{u} \triangleq z-S_{l}$. It was shown in [13] that splitting a (parent) RV using this conditional distribution guarantees that the two resulting RVs $S_{l}$ and $S_{u}$ are i.i.d. This guarantee holds regardless of the target distribution. However, computationally efficient procedures for generating an RV with distribution $f(x \mid z)$ (which $S_{l}$ is) are found only when the target distribution is one of the few "nice" distributions: Gaussian, Cauchy, and Rademacher as shown in [13], and Poisson as will be shown in Subsection 4.5

Among them, Gaussian distribution has a nice property that $S_{l}$ or equivalently the distribution $f(x \mid z)$ can be generated as a linear combination of $z$ and a fresh standard Gaussian RV $Y$ as $S_{l} \triangleq z / 2+\sqrt{n / 2} \cdot Y$, since if we plug Gaussian pdfs $\phi_{n}(\cdot)$ and $\phi_{2 n}(\cdot)$ into (1), $f(x \mid z)$ is precisely the pdf of $\mathcal{N}(z / 2, n / 2)$. Here, $Y$ being "fresh" means it is independent of all other RVs.

This linearly decomposable property has a pleasant consequence that every dyadic range-sum generated by this 1D Gaussian-DST can be recursively decomposed to a linear combination of some i.i.d. standard Gaussian RVs, as illustrated in Figure 1b. In this example, let $Y_{0}, Y_{1}, Y_{2}$ and $Y_{3}$ be four i.i.d. standard Gaussian RVs. The total sum of the universe $S[0,4)$ is written as $2 Y_{0}$, because its distribution is $\mathcal{N}\left(0,2^{2}\right)$. Then, it is split into two half-range-sums $S[0,2) \triangleq Y_{0}+Y_{1}$ and $S[2,4) \triangleq Y_{0}-Y_{1}$ using the linear decomposition

Figure 2 An illustration of the HWT formula $\overrightarrow{\mathbf{y}}=H_{4} \overrightarrow{\mathbf{x}}$.
above with $z=2 Y_{0}$ and a fresh RV $Y_{1}$. Finally, $S[0,2)$ and $S[2,4)$ are similarly split into the four underlying RVs using fresh RVs $Y_{2}$ and $Y_{3}$, respectively.

### 2.2 HWT Representation of 1D Gaussian-DST

It is not hard to verify that, if we apply HWT (to be specified soon) to $X_{0}=Y_{0} / 2+Y_{1} / 2+$ $Y_{2} / \sqrt{2}, X_{1}=Y_{0} / 2+Y_{1} / 2-Y_{2} / \sqrt{2}, X_{2}=Y_{0} / 2-Y_{1} / 2+Y_{3} / \sqrt{2}$, and $X_{3}=Y_{0} / 2-Y_{1} / 2-Y_{3} / \sqrt{2}$, the four HWT coefficients we obtain are precisely $Y_{0}, Y_{1}, Y_{2}, Y_{3}$, respectively. More precisely, we have $\overrightarrow{\mathbf{y}}=H_{4} \overrightarrow{\mathbf{x}}$, where $\overrightarrow{\mathbf{x}} \triangleq\left(X_{0}, X_{1}, X_{2}, X_{3}\right)^{T}, \overrightarrow{\mathbf{y}} \triangleq\left(Y_{0}, Y_{1}, Y_{2}, Y_{3}\right)^{T}$, and $H_{4}$ is the $4 \times 4$ Haar matrix $H_{4}$. This example is illustrated as a matrix-vector multiplication in Figure 2

The above example in which $\Delta=4$ can be generalized to an arbitrary universe size $\Delta$ (that is a power of 2 ) as follows. In general, HWT is defined as $\overrightarrow{\mathbf{w}}=H_{\Delta} \overrightarrow{\mathbf{x}}$, where $\overrightarrow{\mathbf{w}}$ and $\overrightarrow{\mathbf{x}}$ are both $\Delta$-dimensional vectors, and $H_{\Delta}$ is an $\Delta \times \Delta$ Haar matrix. To simplify notations, we drop the subscript $\Delta$ in the sequel. In wavelet terms, $\overrightarrow{\mathbf{x}}$ is called a discrete signal vector and $\overrightarrow{\mathbf{w}}$ is called the HWT coefficient vector. Clearly, the $i^{\text {th }}$ HWT coefficient is the inner product between $\overrightarrow{\mathrm{x}}$ and the $i^{\text {th }}$ row of $H$, for $i=0,1, \cdots, \Delta-1$. In the wavelet theory, we index each HWT coefficient as $W_{j}^{m}\left(\right.$ instead of $\left.W_{i}\right)$ for $m=-1,0,1, \cdots, \log _{2} \Delta-1$ and $j=0,1, \cdots, 2^{m^{+}}-1\left(\right.$ where $\left.m^{+} \triangleq \max \{0, m\}\right)$ in dictionary order of $(m, j)$, and refer to the corresponding row in $H$ (that computes $W_{j}^{m}$ ) as the $H W T$ vector $\overrightarrow{\boldsymbol{\psi}}_{j}^{m}$. Hence we have $W_{j}^{m} \triangleq\left\langle\overrightarrow{\mathbf{x}}, \overrightarrow{\psi_{j}^{m}}\right\rangle$ by definition. In wavelet terms, parameter $m$ is called scale and parameter $j$ is called location. In Figure 2 the 4 HWT coefficients and 4 HWT vectors from top to bottom are on 3 different scales ( $-1,0$, and 1) and are "assigned" 3 different colors accordingly.

We define the indicator vector of a 1 D range $R$, denoted as $\mathbb{1}_{R}$, as a $\Delta$-dimensional $0-1$ vector, the $i^{t h}$ scalar of which takes value 1 if $i \in R$ and 0 otherwise, for $i=0,1, \cdots, \Delta-1$. Throughout this paper, the indicator vectors are the only ones that are not written in boldface with a rightward arrow on the top. We now specify the HWT vectors. Every HWT vector $\overrightarrow{\boldsymbol{\psi}}_{j}^{m}$ is normalized such that $\left\|\vec{\psi}_{j}^{m}\right\|_{2}=1$. The first HWT vector $\overrightarrow{\boldsymbol{\psi}}_{0}^{-1} \triangleq \Delta^{-1 / 2} \cdot \mathbb{1}_{[0, \Delta)}$ is special: Its corresponding coefficient $W_{0}^{-1}$ reflects the scaled (by $\Delta^{-1 / 2}$ ) range-sum of the entire universe, whereas every other HWT coefficient is the (scaled) difference of two range-sums. Every other HWT vector $\vec{\psi}_{j}^{m}$, for $m=0,1, \cdots, \log _{2} \Delta-1$ and $j=0,1, \cdots, 2^{m}-1$, corresponds to the dyadic range $I_{j}^{m} \triangleq\left[j \Delta / 2^{m},(j+1) \Delta / 2^{m}\right)$ in the sense the latter serves as the support of the former: $\vec{\psi}_{j}^{m}$ is defined by setting the first half of $I_{j}^{m}$ to the value $\sqrt{2^{m} / \Delta}$, the second half of $I_{j}^{m}$ to the value $-\sqrt{2^{m} / \Delta}$, and the rest of the universe $[0, \Delta) \backslash I_{j}^{m}$ to the value 0 . Note that $\vec{\psi}_{j}^{m}$ has the same number of scalars with value $\sqrt{2^{m} / \Delta}$ as those with value $-\sqrt{2^{m} / \Delta}$, so $\left\langle\overrightarrow{\boldsymbol{\psi}}_{j}^{m}, \mathbb{1}_{I_{j}^{m}}\right\rangle=0$. From the definition above, $H$ is known to be orthonormal [16], so the following theorem can be applied to it.

- Theorem 1 ([11]). Let $M$ be an $n \times n$ matrix. If $M$ is orthonormal, then it has the following two properties:

1. $M^{T}=M^{-1}$, and $M^{T}$ is also orthonormal.
2. Given any two $n$-dimensional vectors $\overrightarrow{\mathbf{x}}, \overrightarrow{\mathbf{y}}$, we have $\langle\overrightarrow{\mathbf{x}}, \overrightarrow{\mathbf{y}}\rangle=\langle M \overrightarrow{\mathbf{x}}, M \overrightarrow{\mathbf{y}}\rangle$.

Let $\overrightarrow{\mathbf{w}}$ be a $\Delta$-dimensional vector of i.i.d. standard Gaussian RVs. We define the vector of underlying RVs $\overrightarrow{\mathbf{x}}=\left(X_{0}, X_{1}, \cdots, X_{\Delta-1}\right)^{T}$ as $\overrightarrow{\mathbf{x}} \triangleq H^{T} \overrightarrow{\mathbf{w}}$. The underlying RVs defined this way are i.i.d. standard Gaussian, by the following theorem.

- Theorem 2 (Proposition 3.3 .2 in [23]). Let $\overrightarrow{\mathbf{x}}=M \overrightarrow{\mathrm{w}}$ where $M$ is an orthonormal matrix. Then $\overrightarrow{\mathbf{x}}$ is a vector of i.i.d. standard Gaussian RVs if and only if $\overrightarrow{\mathbf{w}}$ is.

We are now ready to state our HWT-based solution to the Gaussian-ERS problem in 1D. Given any range $[l, u)$, we obtain its range-sum $S[l, u)$ by computing $\left\langle\overrightarrow{\mathbf{w}}, H \mathbb{1}_{[l, u)}\right\rangle$, since $S[l, u)=\left\langle\overrightarrow{\mathbf{x}}, \mathbb{1}_{[l, u)}\right\rangle=\left\langle H \overrightarrow{\mathbf{x}}, H \mathbb{1}_{[l, u)}\right\rangle=\left\langle\overrightarrow{\mathbf{w}}, H \mathbb{1}_{[l, u)}\right\rangle$, in which the second equation is by the second property of Theorem $1 \quad\left\langle\overrightarrow{\mathbf{w}}, H \mathbb{1}_{[l, u)}\right\rangle$ can be computed in $O(\log \Delta)$ time, because, by Theorem $3 . H \mathbb{1}_{[l, u)}$ contains $O(\log \Delta)$ nonzero scalars, and by Remark 5 for each such scalar, its index can be located and its value can be computed in $O(1)$ time. Suppose these $O(\log \Delta)$ nonzero scalars are $a_{i_{1}}, a_{i_{2}}, \cdots, a_{i_{k}}$. Then our algorithm is to generate $W_{i_{1}}, W_{i_{2}}, \cdots, W_{i_{k}}$ on demand and return $a_{i_{1}} W_{i_{1}}+a_{i_{2}} W_{i_{2}}+\cdots+a_{i_{k}} W_{i_{k}}$.

- Theorem 3. Given any range $[l, u) \subseteq[0, \Delta), H \mathbb{1}_{[l, u)}$ contains at most $2 \log _{2} \Delta+2$ nonzero scalars.

Theorem 3 is a straightforward corollary of Lemma 4. since $H$ has only $\log _{2} \Delta+1$ scales.

- Lemma 4. Given any range $[l, u) \subseteq[0, \Delta), H \mathbb{1}_{[l, u)}$ contains at most 2 nonzero scalars on each scale.

Proof. On scale $m=-1$, there is only one HWT coefficient anyway, so the claim trivially holds. We next prove the claim for any fixed $m \geq 0$. For each HWT vector $\overrightarrow{\psi_{j}^{m}}, j=$ $0,1, \cdots, 2^{m}-1$, we denote the corresponding HWT coefficient as $r_{j}^{m} \triangleq\left\langle\overrightarrow{\boldsymbol{\psi}}_{j}^{m}, \mathbb{1}_{[l, u)}\right\rangle$. It is not hard to verify that the relationship between the range $[l, u)$ and the dyadic range $I_{j}^{m}$ must be one of the following three cases.

1. $I_{j}^{m}$ and $[l, u)$ are disjoint. In this case, $r_{j}^{m}=0$.
2. $I_{j}^{m} \subseteq[l, u)$. In this case, $r_{j}^{m}=\left\langle\overrightarrow{\boldsymbol{\psi}}_{j}^{m}, \mathbb{1}_{I_{j}^{m}}\right\rangle=0$ as we have shown above.
3. Otherwise, $I_{j}^{m}$ partially intersects $[l, u)$. This case may happen only for at most 2 dyadic ranges: the one that covers $l$ or the one that covers $u$. In this case, $r_{j}^{m}$ can be nonzero.

- Remark 5. Each scalar $r_{j}^{m}$ (in $H \mathbb{1}_{[l, u)}$ ) that may be nonzero can be identified and computed in $O(1)$ time as follows. Note $r_{j}^{m}$ may be nonzero only in the case 3 above, in which case $j$ is equal to either $\left\lfloor l 2^{m} / \Delta\right\rfloor$ or $\left\lfloor u 2^{m} / \Delta\right\rfloor$. As a result, if $r_{j}^{m} \neq 0$, its value can be computed in two steps [21]. First, intersect $[l, u)$ with the first half and the second half of $I_{j}^{m}$, respectively. Second, normalize the following difference by $\sqrt{2^{m} / \Delta}$ : the size of the first intersection minus the size of the second.

The following lemma, which will be used in Section 3 relates to Figure 1a, which shows the generation of any underlying RV involves exactly one split on each level of the DST. It is proved in a way similar to Lemma 4, in which each nonzero scalar $r_{j}^{m}$ corresponds to the unique dyadic range $I_{j}^{m}$ that covers $i$ on scale $m$.

- Lemma 6. Given any $i \in[0, \Delta), H \mathbb{1}_{\{i\}}$ has exactly one nonzero scalar on each scale.

### 2.3 Range-Summable Gaussian RVs in Two Dimensions

Recall that in the 1D case, each HWT coefficient takes the form $W_{j}^{m}$, where $m$ is the scale, and the $j$ is the location. Now, we introduce the two-dimensional (2D) HWT before generalizing our HWT-based ERS solution to 2D. We first explain the outcome of the 2D-HWT before defining its matrix $H^{\otimes 2}$. A 2D-HWT transforms $\Delta^{2}$ numbers, $X_{\overrightarrow{\mathbf{i}}}$ for $\overrightarrow{\mathbf{i}} \in[0, \Delta)^{2}$, to $\Delta^{2}$ HWT coefficients. In the 2D case, each dimension has its own pair of scale and location parameters that is independent of the other dimension. For convenience of presentation, we refer to these two dimensions as vertical (the first) and horizontal (the second), respectively. We denote the vertical scale and location pair as $m_{1}$ and $j_{1}$, and the horizontal pair as $m_{2}$ and $j_{2}$. Each HWT coefficient takes the form $W_{j_{1}, j_{2}}^{m_{1}, m_{2}}$. In the 2D case, there are $\left(\log _{2} \Delta+1\right)^{2}$ scales, namely $\left(m_{1}, m_{2}\right)$ in $\left[-1, \log _{2} \Delta\right)^{2}$. At each scale $\left(m_{1}, m_{2}\right)$, there are $n_{m_{1}, m_{2}} \triangleq 2^{m_{1}^{+}+m_{2}^{+}}$ locations, namely $\left(j_{1}, j_{2}\right)$ for $j_{1} \in\left[0,2^{m_{1}^{+}}\right)$and $j_{2} \in\left[0,2^{m_{2}^{+}}\right)$.

We now give a 2 D example in which $\Delta=4$, and compare it with the earlier 1D example with the same $\Delta$ value. In this 2 D example, there are $\Delta^{2}=16$ HWT coefficients. To facilitate the "color coding" of different scales, we arrange the 16 HWT coefficients into a $4 \times 4$ matrix $\mathbf{W}$ shown in Figure $3 \mathbf{W}$ is the only matrix that we write in boldface in order to better distinguish it from its scalars $\left(W_{j_{1}, j_{2}}^{m_{1}, m_{2}}\right.$ )'s. Figure 3 contains three differently colored rows of heights 1,1 , and 2 respectively, that correspond to vertical scales $m_{1}=-1,0,1$ respectively, and contains three differently colored columns that correspond to the three horizontal scales. Their "Cartesian product" contains 9 "color cells" that correspond to the 9 different scales (values of $\left.\left(m_{1}, m_{2}\right)\right)$. For example, the cell colored in pink corresponds to scale $(1,1)$ and contains 4 HWT coefficients $W_{0,0}^{1,1}, W_{0,1}^{1,1}, W_{1,0}^{1,1}, W_{1,1}^{1,1}$.

Figure 3 The 2D-HWT coefficients, arranged both as a matrix $\mathbf{W}$ and as a flattened vector $\overrightarrow{\mathbf{w}}^{T}$.
We now proceed to describe the 2D-HWT matrix using this $4 \times 4$ example. To do so with best clarity, however, we flatten the $4 \times 4$ matrix of HWT coefficients W into a vector $\overrightarrow{\mathbf{w}}$ of 16 scalars in row-major order, as shown at the bottom of Figure 3. Also, we flatten the underlying RVs, $X_{\overrightarrow{\mathbf{i}}}$ for $\overrightarrow{\mathbf{i}} \in[0, \Delta)^{2}$, into a $\Delta^{2}$-dimensional vector $\overrightarrow{\mathbf{x}}$ arranged in dictionary order of $\overrightarrow{\mathbf{i}}$. With this flattening, in this $4 \times 4$ example, the 2D-HWT can also be compactly written as a matrix-vector multiplication just like in 1D: $\overrightarrow{\mathbf{w}}=H^{\otimes 2} \overrightarrow{\mathbf{x}}$, where $H^{\otimes 2} \triangleq H \otimes H$ is the self Kronecker product (defined next) of $H$.

- Definition 7. Let $A$ be a $p \times q$ matrix and $B$ be a $t \times v$ matrix. Then their Kronecker product $A \otimes B$ is the following pt $\times q v$ matrix.
$A \otimes B \triangleq\left(\begin{array}{ccc}a_{11} B & \cdots & a_{1 q} B \\ \vdots & \ddots & \vdots \\ a_{p 1} B & \cdots & a_{p q} B\end{array}\right)$.
We now state two important theorems concerning the Kronecker product.

## XX:8 On Efficient Range-Summability of IID RVs in Multiple Dimensions

- Theorem 8 (Theorem 13.3 in [11]). Let $P, Q, R, T$ be four matrices such that the matrix products $P \cdot R$ and $Q \cdot T$ are well-defined. Then $(P \otimes Q) \cdot(R \otimes T)=(P \cdot R) \otimes(Q \cdot T)$.
- Theorem 9 (Corollary 13.8 in [11]). The Kronecker product of two orthonormal matrices is also orthonormal.

Our HWT-based ERS solution in 2D is similar to that in 1D. Given a $\Delta^{2}$-dimensional vector $\overrightarrow{\mathbf{w}}$ of i.i.d. standard Gaussian RVs, we define the (flattened) vector of underlying RVs $\overrightarrow{\mathrm{x}} \triangleq\left(H^{\otimes 2}\right)^{T} \overrightarrow{\mathbf{w}}$. The underlying RVs defined in this way are i.i.d. standard Gaussian, because $H^{\otimes 2}$ is also an orthonormal matrix by Theorem 9, so we can apply Theorem 2 just as in the 1D case.

With underlying RVs defined in this way, we can compute the sum of any 2 D range $[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}}) \triangleq\left[l_{1}, u_{1}\right) \times\left[l_{2}, u_{2}\right)$, where $\overrightarrow{\mathbf{l}}=\left(l_{1}, l_{2}\right)^{T}$ and $\overrightarrow{\mathbf{u}}=\left(u_{1}, u_{2}\right)^{T}$, efficiently in a similar way as in the 1 D case. Define the 2 D indicator vector $\mathbb{1}_{[\overrightarrow{\mathbf{r}}, \overrightarrow{\mathbf{u}})}$ as the result of flattening the following $\Delta \times \Delta$ matrix in row-major order: The $\overrightarrow{\mathbf{i}}^{\text {th }}$ scalar in the matrix takes value 1 if $\overrightarrow{\mathbf{i}} \in[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}})$ and takes value 0 otherwise. It is not hard to verify $\mathbb{1}_{[\overrightarrow{1}, \overrightarrow{\mathbf{u}})}=\mathbb{1}_{\left[l_{1}, u_{1}\right)} \otimes \mathbb{1}_{\left[l_{2}, u_{2}\right)}$, and that the following equations still hold in 2D: $S[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}}) \triangleq \sum_{\left(i_{1}, i_{2}\right) \in[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}})} X_{i_{1}, i_{2}}=\left\langle\overrightarrow{\mathbf{x}}, \mathbb{1}_{[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}})}\right\rangle=\left\langle\overrightarrow{\mathbf{w}}, H^{\otimes 2} \mathbb{1}_{[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}})}\right\rangle$. Finally, we can compute $\left\langle\overrightarrow{\mathbf{w}}, H^{\otimes 2} \mathbb{1}_{[\overrightarrow{\mathrm{l}}, \overrightarrow{\mathbf{u}})}\right\rangle$ in $O\left(\log ^{2} \Delta\right)$ time, thanks to the following lemma.

- Lemma 10. For any $2 D$ range $[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}}) \subseteq[0, \Delta)^{2}, H^{\otimes 2} \mathbb{1}_{[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}})}$ has $O\left(\log ^{2} \Delta\right)$ nonzero scalars. Proof. By Theorem $8, H^{\otimes 2} \mathbb{1}_{[\overrightarrow{1}, \overrightarrow{\mathbf{u}})}=(H \otimes H) \cdot\left(\mathbb{1}_{\left[l_{1}, u_{1}\right)} \otimes \mathbb{1}_{\left[l_{2}, u_{2}\right)}\right)=\left(H \mathbb{1}_{\left[l_{1}, u_{1}\right)}\right) \otimes\left(H \mathbb{1}_{\left[l_{2}, u_{2}\right)}\right)$. By Theorem 3 both $H \mathbb{1}_{\left[l_{1}, u_{1}\right)}$ and $H \mathbb{1}_{\left[l_{2}, u_{2}\right)}$ have $O(\log \Delta)$ nonzero scalars, so their Kronecker product has $O\left(\log ^{2} \Delta\right)$ nonzero scalars.

### 2.4 Generalization to Higher Dimensions

Our ERS solution, just like the HWT, can be naturally generalized to higher dimensions as follows. In dimension $d>2$, we continue to have the inverse HWT formula $\overrightarrow{\mathbf{x}} \triangleq M^{T} \overrightarrow{\mathbf{w}}$, where $\overrightarrow{\mathbf{x}}$ is the vector of $\Delta^{d}$ underlying RVs (arranged in dictionary order of $\overrightarrow{\mathbf{i}}$ ), $\overrightarrow{\mathbf{w}}$ is the vector of their HWT coefficients (that are i.i.d. standard Gaussian RVs), and $M$ is the $\Delta^{d} \times \Delta^{d}$ HWT matrix in $d \mathrm{D}$. Here $M \triangleq \underbrace{H \otimes \cdots \otimes H}$ where $H$ is the 1D Haar matrix described above. Since
$M$ is orthonormal by Theorem 9, Theorem 2 continues to hold. Now given a $d \mathrm{D}$ range $[\overrightarrow{\mathrm{l}}, \overrightarrow{\mathbf{u}}) \triangleq$ $\left[l_{1}, u_{1}\right) \times\left[l_{2}, u_{2}\right) \times \cdots \times\left[l_{d}, u_{d}\right)$, its range-sum $S[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}})=\left\langle\overrightarrow{\mathbf{x}}, \mathbb{1}_{[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}})}\right\rangle$ can be computed in $O\left(\log ^{d} \Delta\right)$ time as follows. First, we have $\left\langle\overrightarrow{\mathbf{x}}, \mathbb{1}_{[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}})}\right\rangle=\left\langle M \overrightarrow{\mathbf{x}}, M \mathbb{1}_{[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}})}\right\rangle=\left\langle\overrightarrow{\mathbf{w}}, M \mathbb{1}_{[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}})}\right\rangle$. Then, using similar arguments as in Lemma 10 we can prove that $M \mathbb{1}_{[\overrightarrow{1}, \overrightarrow{\mathbf{u}})}=M \cdot\left(\mathbb{1}_{\left[l_{1}, u_{1}\right)} \otimes \mathbb{1}_{\left[l_{2}, u_{2}\right)} \otimes \cdots \otimes \mathbb{1}_{\left[l_{d}, u_{d}\right)}\right)$ has $O\left(\log ^{d} \Delta\right)$ nonzero scalars.

## 3 The k-wise Independence Theory

In previous sections, for guaranteeing strict all-wise independence among the $\Delta^{2}$ underlying RVs, $X_{\overrightarrow{\mathbf{i}}}$ for $\overrightarrow{\mathbf{i}} \in[0, \Delta)^{2}$, we have made an assumption that each HWT coefficient can be generated on demand by hashing its index using an (idealized) truly random hash function [14], and then mapping the resulting (uniformly distributed) random integer to a Gaussian RV using a deterministic function such as the Box-Muller transform [19]. In this section, we show that, in our HWT-based Gaussian-ERS solution, this assumption on truly random hash functions can be effectively and harmlessly removed in three different ways.

First, for applications that do not require theoretical guarantees, we can use fast "off-the-shelf" hash functions such as wyhash [24] instead of a truly random hash function.

Although these "off-the-shelf" hash functions provide no theoretical guarantee, they can produce a hash value in nanoseconds and ensure empirical independence among its hash values, resulting in underlying RVs that are "i.i.d. enough" for all practical applications. Second, for memory-constrained algorithms (such as the two applications of $d \mathrm{D}$ GaussianERS to be described soon that are both data streaming algorithms), we can use Nisan's pseudorandom generator (PRG) [17] instead, which delivers strong independence guarantees to such algorithms. Third, in the rest of this section, we propose a $k$-wise independence theory and scheme that guarantees that the $\Delta^{d}$ underlying Gaussian RVs are $k$-wise independent, by using $O\left(\log ^{d} \Delta\right) k$-wise independent hash functions (described next) instead. This scheme has the same time complexity of $O\left(\log ^{d} \Delta\right)$ as the (idealized) Gaussian-ERS solution, and has a space complexity also of $O\left(\log ^{d} \Delta\right)$, for storing the seeds of $O\left(\log ^{d} \Delta\right) k$-wise independent hash functions.

A $k$-wise independent hash function $h(\cdot)$ has the following property: Given an arbitrary set of $k$ distinct keys $i_{1}, i_{2}, \cdots, i_{k}$, their hash values $h\left(i_{1}\right), h\left(i_{2}\right), \cdots, h\left(i_{k}\right)$ are independent. Such hash functions are very computationally efficient when $k$ is a small number such as $k=2$ (roughly 2 nanoseconds per hash) and $k=4$ (several nanoseconds per hash) [2, 22, 18. In the following presentation, we assume $d=2$ (2D) for notational simplicity. All of our statements and proofs can be readily generalized to higher dimensions.

In the $k$-wise independence scheme, the underlying RVs are defined as $\overrightarrow{\mathbf{z}} \triangleq\left(H^{\otimes 2}\right)^{T} \overrightarrow{\mathbf{v}}$, where $\overrightarrow{\mathbf{v}}$ is a $\Delta^{2}$-dimensional vector of HWT coefficients like $\overrightarrow{\mathbf{w}}$, but is generated in the following way. Recall in Subsection 2.3 the $\Delta^{2}$ HWT coefficients in $\overrightarrow{\mathbf{v}}$ can be classified into $\left(\log _{2} \Delta+1\right)^{2}$ different scales (colors in Figure 3). For each scale $\left(m_{1}, m_{2}\right)$, we independently fix a $k$-wise independent hash function $h_{m_{1}, m_{2}}(\cdot)$, and compute each HWT coefficient on this scale $\left(m_{1}, m_{2}\right)$, say $V_{j_{1}, j_{2}}^{m_{1}, m_{2}}$, as $g\left(h_{m_{1}, m_{2}}\left(j_{1}, j_{2}\right)\right)$, where $g$ is the aforementioned deterministic function that maps a uniform random integer to a standard Gaussian RV. Since each $h_{m_{1}, m_{2}}(\cdot)$ can be evaluated in practically $O(1)$ time [2], our scheme generates any range-sum in $O\left(\log ^{2} \Delta\right)$ time just like the idealized scheme. The following theorem states that the scalars in $\overrightarrow{\mathbf{z}}$, which are the underlying RVs thus generated, are $k$-wise independent.

- Theorem 11. The vector $\overrightarrow{\mathbf{z}} \triangleq M^{T} \overrightarrow{\mathbf{v}}$, where $M=\left(H^{\otimes 2}\right)$, is comprised of $k$-wise independent standard Gaussian RVs.
Proof. It suffices to prove that any $k$ distinct scalars in $\overrightarrow{\mathbf{z}}$ - say the $i_{1}^{\text {th }}, i_{2}^{\text {th }}, \cdots, i_{k}^{\text {th }}$ scalars are i.i.d. standard Gaussian. Let $\overrightarrow{\mathbf{z}}^{\prime}$ be the $k$-dimensional vector comprised of these $k$ scalars. Let $\left(M^{T}\right)^{\prime}$ be the $k \times \Delta^{2}$ matrix formed by the $i_{1}^{t h}, i_{2}^{t h}, \cdots, i_{k}^{t h}$ rows in $M^{T}$. Then, we have $\overrightarrow{\mathbf{z}}^{\prime}=\left(M^{T}\right)^{\prime} \overrightarrow{\mathbf{v}}$. Recall that if we define $\overrightarrow{\mathbf{w}}$ as a vector of idealized all-wise independent standard Gaussian RVs and $\overrightarrow{\mathbf{x}} \triangleq M^{T} \overrightarrow{\mathbf{w}}$, then $\overrightarrow{\mathbf{x}}$ is also comprised of i.i.d. standard Gaussian RVs by Theorem 2 Now let the random vector $\overrightarrow{\mathbf{x}}^{\prime}$ be defined as $\left(M^{T}\right)^{\prime} \overrightarrow{\mathbf{w}}$. Then $\overrightarrow{\mathbf{x}}^{\prime}$ is comprised of $k$ i.i.d. standard Gaussian RVs, as its scalars are a subset of those of $\overrightarrow{\mathbf{x}}$. Hence, to prove that the scalars in $\overrightarrow{\mathbf{z}}^{\prime}$ are i.i.d. standard Gaussian RVs, it suffices to prove that $\overrightarrow{\mathbf{z}}^{\prime}$ has the same distribution as $\overrightarrow{\mathbf{x}}^{\prime}$.

Recall that in Subsection 2.3, we have classified the HWT coefficients in $\overrightarrow{\mathbf{w}}$ and $\overrightarrow{\mathbf{v}}$, and the columns of $M^{T}$ (called the HWT vectors) into different $\left(m_{1}, m_{2}\right)$ scales (colors). Recall that $n_{m_{1}, m_{2}}$ scalars in $\overrightarrow{\mathbf{w}}$ and $\overrightarrow{\mathbf{v}}$, and accordingly $n_{m_{1}, m_{2}}$ columns of $M^{T}$, have scale ( $m_{1}, m_{2}$ ). Let $\overrightarrow{\mathbf{w}}_{m_{1}, m_{2}}$ and $\overrightarrow{\mathbf{v}}_{m_{1}, m_{2}}$ be the $n_{m_{1}, m_{2}}$-dimensional vectors comprised of the coefficients classified to scale $\left(m_{1}, m_{2}\right)$ in $\overrightarrow{\mathbf{w}}$ and $\overrightarrow{\mathbf{v}}$, respectively. Let $\left(M^{T}\right)_{m_{1}, m_{2}}^{\prime}$ be the $k \times n_{m_{1}, m_{2}}$ matrix comprised of the columns of $\left(M^{T}\right)^{\prime}$ classified to scale $\left(m_{1}, m_{2}\right)$. Then we have $\overrightarrow{\mathbf{z}}^{\prime}=$ $\sum_{\left(m_{1}, m_{2}\right)}\left(M^{T}\right)_{m_{1}, m_{2}}^{\prime} \overrightarrow{\mathbf{v}}_{m_{1}, m_{2}}$ and $\overrightarrow{\mathbf{x}}^{\prime}=\sum_{\left(m_{1}, m_{2}\right)}\left(M^{T}\right)_{m_{1}, m_{2}}^{\prime} \overrightarrow{\mathbf{w}}_{m_{1}, m_{2}}$, where both summations are over all $\left(\log _{2} \Delta+1\right)^{2}$ scales. As explained above, for each scale $\left(m_{1}, m_{2}\right)$, all scalars of $\overrightarrow{\mathbf{v}}_{m_{1}, m_{2}}$ are computed using the same per-scale hash function $h_{m_{1}, m_{2}}(\cdot)$. Since the $\left(\log _{2} \Delta+1\right)^{2}$
per-scale hash functions $h_{m_{1}, m_{2}}(\cdot)$ are independent, the $\left(\log _{2} \Delta+1\right)^{2}$ random vectors in the set $\left\{\left(M^{T}\right)_{m_{1}, m_{2}}^{\prime} \overrightarrow{\mathbf{v}}_{m_{1}, m_{2}} \mid\left(m_{1}, m_{2}\right) \in\left[-1, \log _{2} \Delta\right)^{2}\right\}$ are independent. In the following, we prove that, for any scale ( $m_{1}, m_{2}$ ), the two $k$-dimensional vectors $\left(M^{T}\right)_{m_{1}, m_{2}}^{\prime} \overrightarrow{\mathbf{v}}_{m_{1}, m_{2}}$ and $\left(M^{T}\right)_{m_{1}, m_{2}}^{\prime} \overrightarrow{\mathbf{w}}_{m_{1}, m_{2}}$ have the same distribution, which by Proposition 12 implies that $\overrightarrow{\mathbf{z}}^{\prime}$ and $\overrightarrow{\mathrm{x}}^{\prime}$ have the same distribution.

Now, we fix an arbitrary scale $\left(m_{1}, m_{2}\right)$. Note that each row in $\left(M^{T}\right)_{m_{1}, m_{2}}^{\prime}$ has exactly one nonzero scalar, since the corresponding row in $M^{T}$, or equivalently the corresponding column in $M$, has exactly one nonzero scalar at each scale $\left(m_{1}, m_{2}\right)$, due to Lemma 13 Therefore, although the number of columns in $\left(M^{T}\right)_{m_{1}, m_{2}}^{\prime}$ can be as many as $O\left(\Delta^{2}\right)$, at most $k$ of them, say the $\alpha_{1}^{t h}, \alpha_{2}^{t h}, \cdots, \alpha_{k}^{t h}$ columns, contain nonzero scalars. Then, $\left(M^{T}\right)_{m_{1}, m_{2}}^{\prime} \overrightarrow{\mathbf{v}}_{m_{1}, m_{2}}$ is a weighted sum of only the $\alpha_{1}^{t h}, \alpha_{2}^{t h}, \cdots, \alpha_{k}^{t h}$ scalars in $\overrightarrow{\mathbf{v}}_{m_{1}, m_{2}}$, and these $k$ scalars are i.i.d. Gaussian RVs since they are all generated by the same $k$-wise independent hash function $h_{m_{1}, m_{2}}(\cdot)$. Note that $\left(M^{T}\right)_{m_{1}, m_{2}}^{\prime} \overrightarrow{\mathbf{w}}_{m_{1}, m_{2}}$ is the same (weighted sum) function of the $\alpha_{1}^{t h}, \alpha_{2}^{t h}, \cdots, \alpha_{k}^{t h}$ scalars in $\overrightarrow{\mathbf{w}}_{m_{1}, m_{2}}$, which are also i.i.d. Gaussian RVs by our assumption. Hence, $\left(M^{T}\right)_{m_{1}, m_{2}}^{\prime} \overrightarrow{\mathbf{v}}_{m_{1}, m_{2}}$ has the same distribution as $\left(M^{T}\right)_{m_{1}, m_{2}}^{\prime} \overrightarrow{\mathbf{w}}_{m_{1}, m_{2}}$.

- Proposition 12. Suppose random vectors $\overrightarrow{\mathbf{x}}$ and $\overrightarrow{\mathbf{z}}$ each is the sum of $N$ independent random vectors as follows: $\overrightarrow{\mathbf{x}}=\overrightarrow{\mathbf{x}}_{1}+\overrightarrow{\mathbf{x}}_{2}+\cdots+\overrightarrow{\mathbf{x}}_{N}$ and $\overrightarrow{\mathbf{z}}=\overrightarrow{\mathbf{z}}_{1}+\overrightarrow{\mathbf{z}}_{2}+\cdots+\overrightarrow{\mathbf{z}}_{N}$. Then, $\overrightarrow{\mathbf{x}}$ and $\overrightarrow{\mathbf{z}}$ have the same distribution if each pair of components $\overrightarrow{\mathbf{x}}_{i}$ and $\overrightarrow{\mathbf{z}}_{i}$ have the same distribution, for $i=1,2, \cdots, N$.
- Lemma 13. Any column of $M=H^{\otimes 2}$, which is equal to $H^{\otimes 2} \mathbb{1}_{\{\overrightarrow{\mathbf{i}}\}}$ for some $\overrightarrow{\mathbf{i}}=\left(i_{1}, i_{2}\right)^{T}$, has exactly one nonzero scalar on each scale $\left(m_{1}, m_{2}\right)$.

Proof. The 2D indicator vector can be decomposed to the Kronecker product of two 1D indicator vectors as $\mathbb{1}_{\{\overrightarrow{\mathbf{i}}\}}=\mathbb{1}_{\left\{i_{1}\right\}} \otimes \mathbb{1}_{\left\{i_{2}\right\}}$, so $H^{\otimes 2} \mathbb{1}_{\{\overrightarrow{\mathbf{i}}\}}=\left(H \mathbb{1}_{\left\{i_{1}\right\}}\right) \otimes\left(H \mathbb{1}_{\left\{i_{2}\right\}}\right)$. The claim above follows from Lemma 6 .

## 4 Multidimensional Dyadic Simulation

### 4.1 Hardness of Multidimensional Dyadic Simulation

As explained earlier, in one dimension (1D), any dyadic range-sum $S[l, u)$, no matter what the target distribution is, can be computed by performing $O(\log \Delta)$ binary splits along the path from the root $S[0, \Delta)$ to the node $S[l, u)$ in the dyadic simulation tree (DST). Since we have just efficiently generalized the Gaussian-DST approach (equivalent to the HWT-based approach) to any dimension $d \geq 2$, we wonder whether we can do the same for all target distributions. By "efficiently", we mean that a generalized solution should be able to compute any $d \mathrm{D}$ range-sum in $O\left(\log ^{d} \Delta\right)$ time and space like in the Gaussian case.

Unfortunately, it appears hard, if not impossible, to generalize the DST approach to $d \mathrm{D}$ for arbitrary target distributions. We have identified a sufficient condition on the target distribution for such an efficient generalization to exist. We prove the sufficiency by proposing a DST-based universal algorithmic framework, to be described in Subsection 4.4 that solves the $d \mathrm{D}-E R S$ problem for any target distribution satisfying this condition. Unfortunately, so far only two distributions, namely Gaussian and Poisson, are known to satisfy this condition, as will be elaborated in Subsection 4.2 We will also describe in Subsection 4.3 two example distributions that do not satisfy this sufficient condition, namely Cauchy and Rademacher. In the following, we specify this condition and explain why it is "almost necessary".

For ease of presentation, in the following, we fix the number of dimensions $d$ at 2 until the end of Subsection 4.4 In a 2D universe, we can say that any 2D range is the Cartesian product of its horizontal and vertical 1D ranges. We say a 2 D range is dyadic if and only if its horizontal and vertical 1D ranges are both dyadic. Since any general (not necessarily dyadic) 1D range can be "pieced together" using $O(\log \Delta) 1 \mathrm{D}$ dyadic ranges [20], it is not hard to show, using the Cartesian product argument, that any general 2D range can be "pieced together" using $O\left(\log ^{2} \Delta\right) 2 \mathrm{D}$ dyadic ranges. Hence in the following, we focus on the computation (generation) of only 2D dyadic range-sums.

We need to introduce some additional notations. Like before, we assume all underlying RVs, $X_{i_{1}, i_{2}}$ for $\left(i_{1}, i_{2}\right)$ in the 2D universe $[0, \Delta)^{2}$, are i.i.d. with a certain target distribution $X$. We define each horizontal strip-sum $S_{i}^{H} \triangleq X_{i, 0}+X_{i, 1}+\cdots+X_{i, \Delta-1}$ for $i \in[0, \Delta)$ as the sum of range $[i, i+1) \times[0, \Delta)$, and each vertical strip-sum $S_{i}^{V} \triangleq X_{0, i}+X_{1, i}+\cdots+X_{\Delta-1, i}$ for $i \in[0, \Delta)$ as the sum of range $[0, \Delta) \times[i, i+1)$. We denote as $S$ the total sum of all underlying RVs in the universe, i.e., $S \triangleq \sum_{i_{1}=0}^{\Delta-1} \sum_{i_{2}=0}^{\Delta-1} X_{i_{1}, i_{2}}=\sum_{i=0}^{\Delta-1} S_{i}^{H}=\sum_{i=0}^{\Delta-1} S_{i}^{V}$.

Now we are ready to state this sufficient condition. For ease of presentation, we break it down into two parts. The first part, stated in the following formula, states that the vector of vertical strip-sums and the vector of horizontal strip-sums in $[0, \Delta)^{2}$ are conditionally independent given the total sum $S$.

$$
\begin{equation*}
\left(S_{0}^{V}, S_{1}^{V}, \cdots, S_{\Delta-1}^{V}\right) \Perp\left(S_{0}^{H}, S_{1}^{H}, \cdots, S_{\Delta-1}^{H}\right) \mid S \tag{2}
\end{equation*}
$$

The second part is that this conditional independence relation holds for the two corresponding vectors in any 2D dyadic range (that is not necessarily a square). Intuitively, this condition says that how a 2D dyadic range-sum is split horizontally is conditionally independent (upon this 2D range-sum) of how it is split vertically. Roughly speaking, this condition implies that the 1D-DST governing the horizontal splits is conditionally independent of the other 1D-DST governing the vertical splits. Hence, our DST-based universal algorithmic framework for 2D can be viewed as the Cartesian product of the two 1D-DSTs, as will be elaborated in Subsection 4.4

In the following, we offer some intuitive evidence why this condition is likely necessary. Without loss of generality, we consider the generation of an arbitrary horizontal strip-sum $S_{i_{1}}^{H}$ conditional on the vertical strip-sums $\left(S_{0}^{V}, S_{1}^{V}, \cdots, S_{\Delta-1}^{V}\right)$. Suppose 22 does not hold, which means $\left(S_{0}^{H}, S_{1}^{H}, \cdots, S_{\Delta-1}^{H}\right)$ is not conditionally independent of ( $S_{0}^{V}, S_{1}^{V}, \cdots, S_{\Delta-1}^{V}$ ) given $S$. Then the distribution of $S_{i_{1}}^{H}$ is arguably parameterized by the values (realizations) of all $\Delta$ vertical strip-sums $\left(S_{0}^{V}, S_{1}^{V}, \cdots, S_{\Delta-1}^{V}\right)$, since $S_{1_{1}}^{H}$ and any vertical strip-sum $S_{i_{2}}^{V}$ for $i_{2} \in[0, \Delta)$ are in general dependent RVs by Theorem 14 Hence, unless some magic happens (which we cannot rule out rigorously), to generate (realize) the RV $S_{i_{1}}^{H}$, conceivably we need to first realize all $\Delta \mathrm{RVs}\left(S_{0}^{V}, S_{1}^{V}, \cdots, S_{\Delta-1}^{V}\right)$, the time and space complexities of which are both $\Omega(\Delta)$.

- Theorem 14. For any $\left(i_{1}, i_{2}\right)$ in $[0, \Delta)^{2}, S_{i_{1}}^{H}$ and $S_{i_{2}}^{V}$ are dependent unless the target distribution $X$ satisfies $\operatorname{Pr}[X=c]=1$ for some constant $c$.

This theorem is rather intuitive but has a nontrivial proof, which is given in Appendix A in the interest of space.

### 4.2 Two Known Positive Cases: Gaussian and Poisson

When the target distribution is Gaussian, it can be shown that the vector of vertical strips $\left(S_{0}^{V}, S_{1}^{V}, \cdots, S_{\Delta-1}^{V}\right)$ is a function only of all the HWT coefficients in the form of $W_{0, j_{2}}^{-1, m_{2}}$

## XX:12 On Efficient Range-Summability of IID RVs in Multiple Dimensions

(for some scale $m_{2}$ and location $j_{2}$ ), which are the $\Delta$ scalars on the first row (from the top) of $\overrightarrow{\mathrm{w}}$ arranged into a $\Delta \times \Delta$ matrix (like that shown in Figure 3); we denote these HWT coefficients as a vector $\overrightarrow{\mathbf{w}}^{V}$. It can be shown that the vector of horizontal strips $\left(S_{0}^{H}, S_{1}^{H}, \cdots, S_{\Delta-1}^{H}\right)$ is a function only of all the HWT coefficients in the form of $W_{j_{1}, 0}^{m_{1},-1}$ (for some scale $m_{1}$ and location $j_{1}$ ), which are the $\Delta$ scalars on the first column (from the left) of $\overrightarrow{\mathbf{w}}$ in the same matrix form as above; we denote these HWT coefficients as a vector $\overrightarrow{\mathbf{w}}^{H}$. Since all the $\Delta^{2}$ HWT coefficients are i.i.d. Gaussian (due to Theorem 2 and that the underlying RVs are i.i.d. Gaussian), $\left(S_{0}^{V}, S_{1}^{V}, \cdots, S_{\Delta-1}^{V}\right)$ and $\left(S_{0}^{H}, S_{1}^{H}, \cdots, S_{\Delta-1}^{H}\right)$ are independent conditioned upon $S$, because the two vectors $\overrightarrow{\mathbf{w}}^{H}$ and $\overrightarrow{\mathbf{w}}^{V}$ share only a single common element: $W_{0,0}^{-1,-1}=1 / \Delta \cdot \sum_{i_{1}=0}^{\Delta-1} \sum_{i_{2}=0}^{\Delta-1} X_{i_{1}, i_{2}}=S / \Delta$.

To prove that Poisson satisfies the sufficient condition, we need to introduce the following "balls-into-bins" process. Mathematically but not computationally, we independently throw $S$ balls each uniformly and randomly into one of the $\Delta^{2}$ bins arranged as a $\Delta \times \Delta$ matrix indexed by $\left(i_{1}, i_{2}\right) \in[0, \Delta)^{2}$. Each underlying $X_{i_{1}, i_{2}}$ is defined as the number of balls that end up in the bin indexed by $\left(i_{1}, i_{2}\right)$. It is not hard to verify that, given the total sum $S$, the $\Delta^{2}$ underlying RVs generated by the "balls-into-bins" process have the same conditional (upon their total sum being $S$ ) joint distribution as $\Delta^{2}$ i.i.d. Poisson RVs. Note that throwing a ball uniformly and randomly into a bin consists of the following two independent steps. The first step is to select $i_{1}$ uniformly from $[0, \Delta)$ and throw the ball to the $i_{1}^{\text {th }}$ row (thus increasing the horizontal strip-sum $S_{i_{1}}^{H}$ by 1 ). The second step is to select $i_{2}$ uniformly from $[0, \Delta)$ and throw the ball to the $i_{2}^{t h}$ column (thus increasing the vertical strip-sum $S_{i_{2}}^{V}$ by 1). Therefore, $\left(S_{0}^{V}, S_{1}^{V}, \cdots, S_{\Delta-1}^{V}\right)$ and $\left(S_{0}^{H}, S_{1}^{H}, \cdots, S_{\Delta-1}^{H}\right)$ are conditionally independent given $S$, because these two steps, in throwing each of the $S$ balls, are independent.

### 4.3 Two Example Negative Cases: Rademacher and Cauchy

As the negative cases are shown by counterexamples, we set $\Delta$ to a small number 2 to make this job easier. In this case we are dealing with only 4 underlying RVs $X_{0,0}, X_{0,1}, X_{1,0}$, and $X_{1,1}$. We start with the target distribution being Rademacher $(\operatorname{Pr}[X=1]=\operatorname{Pr}[X=0]=0.5)$. We prove by contradiction. Suppose $S_{0}^{V}$ is independent of $\left(S_{0}^{H}, S_{1}^{H}\right)$ conditioned on $S$. We have $\operatorname{Pr}\left(S_{0}^{V}=0 \mid S=0\right) \operatorname{Pr}\left(S_{0}^{H}=2, S_{1}^{H}=-2 \mid S=0\right)=\operatorname{Pr}\left(S_{0}^{V}=0 \mid S_{0}^{H}=2, S_{1}^{H}=\right.$ $-2, S=0) \operatorname{Pr}\left(S_{0}^{H}=2, S_{1}^{H}=-2 \mid S=0\right)$, since both the LHS and the RHS are equal to $\operatorname{Pr}\left(S_{0}^{V}=0, S_{0}^{H}=2, S_{1}^{H}=-2 \mid S=0\right) \neq 0$. Hence, we obtain $\operatorname{Pr}\left(S_{0}^{V}=0 \mid S=\right.$ $0)=\operatorname{Pr}\left(S_{0}^{V}=0 \mid S_{0}^{H}=2, S_{1}^{H}=-2, S=0\right)$. It is not hard to calculate using (1) that $\operatorname{Pr}\left(S_{0}^{V}=0 \mid S=0\right)=2 / 3$. However, $\operatorname{Pr}\left(S_{0}^{V}=0 \mid S_{0}^{H}=2, S_{1}^{H}=-2, S=0\right)=1$, because $S_{0}^{H}=2$ implies $X_{0,0}=1$ and $S_{1}^{H}=-2$ implies $X_{1,0}=-1$, and as a result $S_{0}^{V}=X_{0,0}+X_{1,0}=0$ with probability 1 . Therefore, we have a contradiction.

- Remark. The authors in [15] were looking for a 2D-ERS solution for Rademacher RVs with (approximately) 4 -wise independence guarantee. The fact that (2) does not hold likely rules out a DST-based ERS solution that works in 2D. However, it does not rule out a generalization of 1D ECC-based ERS schemes such as EH3 [4] to 2D, although no such generalization has been discovered to this day [20].

Now we move on to the target distribution being Cauchy. Suppose $S_{0}^{H}=z$ and $S_{1}^{H}=-z$ for a real number $z$ such that $S=S_{0}^{H}+S_{1}^{H}=0$. It can be shown that (e.g., in 13]) $X_{0,0}$ has conditional pdf $f(x \mid z)=\left(4+z^{2}\right) /\left(2 \pi\left(1+x^{2}\right)\left(1+(z-x)^{2}\right)\right)$, and that $X_{1,0}$ has pdf $f(x \mid-z)$. Hence, $S_{0}^{V}$ has pdf $g(x \mid z)=f(x \mid z) * f(x \mid-z)$, where $*$ refers to the convolution on $x$. We consider the value of $g(x \mid z)$ at $x=0$. We have $g(0 \mid z)=\int_{-\infty}^{\infty} f(x \mid z) \cdot f(-x \mid-z) \mathrm{d} x=$ $\left(4+z^{2}\right)^{2} /\left(4 \pi^{2}\right) \cdot \int_{-\infty}^{\infty} 1 /\left(\left(1+x^{2}\right)^{2}\left(1+(z-x)^{2}\right)^{2}\right) \cdot \mathrm{d} x=\left(20+z^{2}\right) /\left(4 \pi\left(4+z^{2}\right)\right)$. Since $g(0 \mid z)$

Figure 4 An example of the universal algorithmic framework in 2 D with $\Delta=8$.
is still a function of $z$, we conclude $S_{0}^{V}$ is dependent on $\left(S_{0}^{H}, S_{1}^{H}\right)$ given $S$.

### 4.4 The DST-Based Universal Algorithmic Framework for 2D and dD

In this section, we describe the universal algorithmic framework that can be instantiated to compute the sum of any 2D dyadic range in $O\left(\log ^{2} \Delta\right)$ time and space. Interestingly, the time and the space complexities of computing any general 2D range-sum remain $O\left(\log ^{2} \Delta\right)$, as we will explain shortly. This framework is simply to perform a 4 -way-split procedure recursively on all ancestors (defined next) of the 2D dyadic range whose sum is to be computed (generated). In a 4 -way-split procedure, we compute a 2 D dyadic range-sum say $S[\overrightarrow{\mathrm{l}}, \overrightarrow{\mathbf{u}})$ by splitting the sum of its lattice grandparent, which is the unique (if it exists) 2D dyadic range that contains $[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}})$ and is twice as large along both horizontal and vertical dimensions, into four pieces.

We illustrate this procedure by a tiny example (with universe size $\Delta=8$ ) shown in Figure 4 . Our computation task is to generate the sum of the 2 D dyadic range $[6,7) \times[6,8)$ that is shadowed and marked as region II in Figure 4 We call the region I + II its horizontal parent, since it contains II and is twice as large in the horizontal dimension. Similarly, we call the region II + IV its vertical parent. Its lattice grandparent is the union of the 4 regions I + II + III + IV. We refer to the horizontal and the vertical parents, and the lattice grandparent, of a 2D dyadic range as its direct generation ancestors (DGAs).

In this example, the sum of the 2 D range $[6,7) \times[6,8)$ is to be generated according to a conditional distribution parameterized by the sums of its three DGAs. To do so, however, the sum of each such DGA is to be generated according to the sums of the DGA's three DGAs, and so on. Given any 2D dyadic range, since it has $O\left(\log ^{2} \Delta\right)$ distinct ancestors (DGAs, DGAs' DGAs, and so on), we can generate its sum in $O\left(\log ^{2} \Delta\right)$ time and space, by arranging the computations of the sums of these $O\left(\log ^{2} \Delta\right)$ ancestors in the dynamic programming order. One can think of these $O\left(\log ^{2} \Delta\right) 4$-way-split procedures as the Cartesian product of the $O(\log \Delta)$ binary splits along the horizontal 1D-DST and those along the vertical 1D-DST. As explained in Subsection 4.1 the sufficient condition makes taking this Cartesian product possible.

In a 4-way-split procedure, degenerated cases arise when the 2D dyadic range whose sum is to be generated spans the entire 1D universe on either dimension or on both dimensions. In the former case, this 2D dyadic range has only one parent and no lattice grandparent. For example, the range $[4,6) \times[0,8)$ has only a vertical parent $[4,8) \times[0,8)$. In this case, the 4 -way-split degenerates to the 2 -way split in 1D as already explained in (1). In the latter case, which is the only boundary condition of the aforementioned dynamic programming, the

2D dyadic range is the entire 2D universe. In this case, its sum is directly generated from the distribution $X^{* \Delta^{2}}$. In the cases of both Gaussian and Poisson target distributions, $X^{* \Delta^{2}}$ takes a simple form and can be generated efficiently [19, 12].

Although we have only explained why a 2D dyadic range-sum can be generated in $O\left(\log ^{2} \Delta\right)$ time and space, we can actually prove that any general 2 D range-sum can also be generated in $O\left(\log ^{2} \Delta\right)$ time and space. The proof is similar to that of Corollary 1 in 13 and is based on the following two observations. First, any 2D range can be "pieced together" using $O\left(\log ^{2} \Delta\right)$ 2D dyadic ranges as stated before. Second, these $O\left(\log ^{2} \Delta\right) 2 \mathrm{D}$ dyadic ranges together have only $O\left(\log ^{2} \Delta\right)$ distinct ancestors.

We can generalize the universal algorithmic framework above to $d \mathrm{D}$. In the generalized framework, the 2 -way conditional independence relation in 2D becomes a $d$-way conditional independence relation in $d \mathrm{D}$, and the 4 -way-split procedure in 2 D becomes a $2^{d}$-way-split procedure in $d \mathrm{D}$. We omit the details of this generalization in the interest of space.

### 4.5 The 4-Way-Split Procedure for Poisson

While the algorithmic framework of performing 4-way splits recursively is the same for any target distribution that satisfies the sufficient condition, the exact 4 -way-split procedure is different for each such target distribution. In the following, we specify only the 4 -way-split procedure for Poisson, since that for Gaussian has already been seamlessly "embedded" in the HWT-based solution. Suppose given a 2D dyadic range $[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}})$, we need to compute $S[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}})$ by performing a 4 -way split. We denote as $S_{h}, S_{v}$, and $S_{g}$ the sums of the horizontal parent, the vertical parent, and the lattice grandparent of $[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}})$, respectively. Then $S[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}})$ is generated using the following conditional distribution:

$$
\begin{equation*}
\operatorname{Pr}\left(S[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}})=x \mid S_{h}=s_{h}, S_{v}=s_{v}, S_{g}=s_{g}\right)=1 / c \cdot f\left(x \mid s_{h}, s_{v}, s_{g}\right), \tag{3}
\end{equation*}
$$

where $f\left(x \mid s_{h}, s_{v}, s_{g}\right)=1 /\left(x!\left(s_{h}-x\right)!\left(s_{v}-x\right)!\left(s_{g}-s_{h}-s_{v}+x\right)!\right)$ and $c \triangleq \sum_{y=0}^{\infty} f(y \mid$ $\left.s_{h}, s_{v}, s_{g}\right)$ is a normalizing constant. As explained, in a degenerated case, this split is the same as a 2-way split in the 1D case. In the case of Poisson, by plugging the Poisson pmfs $\phi_{n}(x)=e^{-n} n^{x} /(x!)$ and $\phi_{2 n}(x)=e^{-2 n}(2 n)^{x} /(x!)$ into (1), we obtain $f(x \mid z)=2^{-z}\binom{z}{x}$, which is the pmf of $\operatorname{Binomial}(z, 1 / 2)$.

## 5 Applications of Multi-Dimensional ERS

In this section, we introduce two important applications of our HWT-based $d \mathrm{D}$ Gaussian-ERS solution. The first application is to the problem of fast approximate wavelet tracking (FAWT) on data streams [6, 3]. Our FAWT solution can be applied in the same way to another provably equivalent problem called space-efficient histogram maintenance (SEHM) on data streams [5, 15].

We first introduce the FAWT problem in 1D [6], or 1D-FAWT for short. In this problem, the precise system state is comprised of a $\Delta$-dimensional vector $\overrightarrow{\mathbf{s}}$, each scalar of which is a counter. The precise system state at any moment of time is determined by a data stream, in which each data item is an update to one such counter (called a point update) or all counters in a 1 D range (called a range update). In 1D-FAWT, $\overrightarrow{\mathbf{s}}$ is considered a $\Delta$-dimensional signal vector that is constantly "on the move" caused by the updates in the data stream. Let $\overrightarrow{\mathbf{r}}$ be the ( $\Delta$-dimensional) vector of HWT coefficients of $\overrightarrow{\mathbf{s}}$. Clearly, $\overrightarrow{\mathbf{r}}$ is also a "moving target". In 1D-FAWT, the goal is to closely track (the precise value of) $\overrightarrow{\mathbf{r}}$ over time using a sketch, in the sense that at moment $t$, we can recover from the sketch an estimate of $\overrightarrow{\mathbf{r}}_{t}$, denoted as $\overrightarrow{\mathbf{r}}_{t}^{\prime}$,
such that $\left\|\overrightarrow{\mathbf{r}}_{t}-\overrightarrow{\mathbf{r}}_{t}^{\prime}\right\|_{2}$ is small. An acceptable solution should use a sketch whose size (space complexity) is only $O(\operatorname{poly} \log (\Delta))$, and be able to maintain the sketch with a computation time cost of $O(\operatorname{polylog}(\Delta))$ per point or range update.

The first solution to 1D-FAWT was proposed in [6]. It requires the efficient computation of an arbitrary scalar in $H \overrightarrow{\mathbf{x}}$, where $H$ is the $\Delta \times \Delta$ Haar matrix and $\overrightarrow{\mathbf{x}}$ is a $\Delta$-dimensional vector of 4 -wise independent Rademacher RVs. This computation problem boils down to the ERS of 4-wise independent Rademacher RVs in 1D, which was tackled in [6] using an ECC-based solution. Authors of [15] stated that if they could find a solution to this ERS problem in $d \mathrm{D}$, then the 1D-FAWT solution in 6] would become a $d \mathrm{D}$-FAWT solution. The first solution to $d \mathrm{D}-\mathrm{FAWT}$, proposed in [3], explicitly bypassed this ERS problem. We discover that if we replace the $\overrightarrow{\mathbf{x}}$ in the 1D-FAWT solution above with a $\Delta$-dimensional vector of 4 -wise independent standard Gaussian RVs, we can generalize it to a $d \mathrm{D}$-FAWT solution that has the same time and space complexities as [3]. With this replacement, the resulting $d \mathrm{D}$ Gaussian-ERS problem on 4-wise independent underlying RVs can be solved using our $k$-wise ( $k=4$ ) independence scheme proposed in Section 3

Our second application is to the problem of approximately answering range-sum queries over a data cube that is similarly "on the move" propelled by the (point or range) updates that arrive in a stream. This problem can be formulated as follows. The precise system state is comprised of $\Delta^{d}$ counters that are "on the move". Given a range $[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}})$ at moment $t$, the goal is to approximately compute the sum of counter values in this range $C[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}}) \triangleq \sum_{\overrightarrow{\mathbf{i}} \in[\overrightarrow{\mathbf{l}}, \overrightarrow{\mathbf{u}})} \sigma_{\overrightarrow{\mathbf{i}}}(t)$, where $\sigma_{\overrightarrow{\mathbf{i}}}(t)$ is the value of the counter $\sigma_{\overrightarrow{\mathbf{i}}}$ at moment $t$. A desirable solution to this problem in $d \mathrm{D}$ should satisfy three requirements (in which multiplicative terms related to the desired $(\epsilon, \delta)$ accuracy bound are ignored). First, any range-sum query is answered in $O\left(\log ^{d} \Delta\right)$ time. Second, its space complexity is $O\left(\log ^{d} \Delta\right)$ words (each of which is $O(\log \Delta)$ bits in length). Third, every point or range update to the system state is processed in $O\left(\log ^{d} \Delta\right)$ time. Until this paper, no solution that satisfies all three requirements has been found for this problem in $d \mathrm{D}$ for any $d \geq 2$. For example, solutions producing exact answers (to the range queries) [7, 21, 8] all require $O\left(\Delta^{d} \log \Delta\right)$ space and hence do not satisfy the second requirement; and Haar + tree [10] works only on static data, and hence does not satisfy the third requirement.

In 1D, a solution that satisfies all three requirements (with $d=1$ ) was proposed in [6, 5]. It involves 1D-ERS computations on 4-wise independent underlying RVs where the target distribution is either Gaussian or Rademacher, which are tackled using a DST-based [5] or a ECC-based [6] 1D-ERS solution, respectively. This range-sum query solution can be readily generalized to $d \mathrm{D}$ if the ERS computations above can be performed in $d \mathrm{D}$. This gap is filled by our $k$-wise $(k=4)$ independence scheme for $d \mathrm{D}$ Gaussian-ERS, resulting in the first solution to this problem for $d \geq 2$ that satisfies all three requirements.

## 6 Conclusion

In this work, we propose a novel framework to $d \mathrm{D}-E R S$ on RVs that have Gaussian or Poisson distribution. Our solutions are the first ones that compute any rectangular range-sum of the RVs in polylogarithmic time. We develop a novel $k$-wise independence theory that provides both high computational efficiencies and strong provable independence guarantees. Finally, we generalize existing DST-based solutions for 1D-ERS to 2D, and characterize a sufficient and likely necessary condition on the target distribution for this generalization to be feasible.

## A Proof of Theorem 14

Proof. Note that for any $\left(i_{1}, i_{2}\right)$ in $[0, \Delta)^{2}, S_{i_{1}}^{H}$ intersects $S_{i_{2}}^{V}$ on exactly one underlying RV $X_{i_{1}, i_{2}}$, so $S_{i_{1}}^{H}-X_{i_{1}, i_{2}}, S_{i_{2}}^{V}-X_{i_{1}, i_{2}}$, and $X_{i_{1}, i_{2}}$ are independent. By Lemma 15, $S_{i_{1}}^{H}$ and $S_{i_{2}}^{V}$ are always dependent unless there exists some constant $c$ such that $\operatorname{Pr}\left[X_{i_{1}, i_{2}}=c\right]=1$.

- Lemma 15. Let $X, Y, Z$ be three independent $R V$ s. Suppose $X+Z$ and $Y+Z$ are independent. Then there exists some constant $c$ such that $\operatorname{Pr}[Z=c]=1$.

Proof. Let $a, b$ be two arbitrary real numbers. Denote as $F_{X}(\cdot)$ and $F_{Y}(\cdot)$ the cumulative distribution functions (cdfs) of $X$ and $Y$, respectively. Denote as $\mathbb{1}_{\mathcal{E}}$ the indicator RV of an event $\mathcal{E}$, which has value 1 if $\mathcal{E}$ happens and 0 otherwise. Then, $\operatorname{Pr}(X+Z \leq a)=$ $E\left[\mathbb{1}_{X+Z \leq a}\right]=E\left[E\left[\mathbb{1}_{X \leq a-Z} \mid Z\right]\right]=E\left[F_{X}(a-Z)\right]$, where the second equation is by the total expectation formula, and the third equation is because $X$ and $Z$ are independent (so the conditional cdf of $X \mid Z$ is also $\left.F_{X}(\cdot)\right)$. Similarly, we have $\operatorname{Pr}(Y+Z \leq b)=E\left[F_{Y}(b-Z)\right]$ and $\operatorname{Pr}(X+Z \leq a, Y+Z \leq b)=E\left[F_{X}(a-Z) F_{Y}(b-Z)\right]$. Therefore, $\operatorname{Pr}(X+Z \leq a, Y+Z \leq$ b) $-\operatorname{Pr}(X+Z \leq a) \operatorname{Pr}(Y+Z \leq b)=E\left[F_{X}(a-Z) F_{Y}(b-Z)\right]-E\left[F_{X}(a-Z)\right] E\left[F_{Y}(b-Z)\right]=$
$\operatorname{Cov}\left(F_{X}(a-Z), F_{Y}(b-Z)\right)$. This covariance always exists since cdfs are bounded functions. Since $X+Z$ and $Y+Z$ are independent, $\operatorname{Pr}(X+Z \leq a, Y+Z \leq b)=\operatorname{Pr}(X+Z \leq$ a) $\operatorname{Pr}(Y+Z \leq b)$, so $\operatorname{Cov}\left(F_{X}(a-Z), F_{Y}(b-Z)\right)=0$.

We prove by contradiction. Suppose $Z$ is not with probability 1 a constant. Then for any set $\mathcal{I}$ such that $\operatorname{Pr}(Z \in \mathcal{I})=1, \mathcal{I}$ must contain at least two numbers. Let $z_{1}<z_{2}$ be two such numbers such that the pdf (or pmf) of $Z$ is nonzero at $z_{1}$ and $z_{2}$. Since both $F_{X}(a-Z)$ and $F_{Y}(b-Z)$ are non-increasing functions of $Z$, and $\operatorname{Cov}\left(F_{X}(a-Z), F_{Y}(b-Z)\right)=0$, either $F_{X}(a-Z)$ or $F_{Y}(b-Z)$ must be a constant with probability 1 by Theorem 16 Without loss of generality, suppose $F_{X}(a-Z)$ is a constant with probability 1. Then, $F_{X}\left(a-z_{1}\right)=F_{X}\left(a-z_{2}\right)$ holds for arbitrary values of $a$. Define a sequence $x_{0} \triangleq z_{1}, x_{1} \triangleq z_{1}+\left(z_{2}-z_{1}\right), x_{2} \triangleq$ $z_{1}+2 \cdot\left(z_{2}-z_{1}\right), \cdots, x_{k} \triangleq z_{1}+k \cdot\left(z_{2}-z_{1}\right), \cdots$ such that we have $\lim _{i \rightarrow \infty} x_{i}=\infty$. Then, we have $F_{X}\left(x_{0}\right)=F_{X}\left(x_{1}\right)=F_{X}\left(x_{2}\right)=\cdots$, where the $k$-th equation $F_{X}\left(x_{k-1}\right)=F_{X}\left(x_{k}\right)$ is by applying $F_{X}\left(a-z_{2}\right)=F_{X}\left(a-z_{1}\right)$ with $a=2 z_{1}+k \cdot\left(z_{2}-z_{1}\right)$. Since $\lim _{i \rightarrow \infty} x_{i}=$ $\infty$, we have $F_{X}\left(x_{0}\right)=\liminf _{i \rightarrow \infty} F_{X}\left(x_{i}\right) \geq \liminf _{x \rightarrow \infty} F_{X}(x)$. Similarly, we can prove $F_{X}\left(x_{0}\right) \leq \lim \sup _{x \rightarrow-\infty} F_{X}(x)$. By the properties of cdf, we have $\lim \inf _{x \rightarrow \infty} F_{X}(x)=1$ and $\lim \sup _{x \rightarrow-\infty} F_{X}(x)=0$. As a result, we have proved $0 \geq 1$, which is a contradiction.

- Theorem 16 ([9]). Let $Z$ be an $R V$, and $f(\cdot)$ and $g(\cdot)$ be two non-increasing functions. Then the covariance $\operatorname{Cov}(f(Z), g(Z)) \geq 0$ if it exists. Furthermore, $\operatorname{Cov}(f(Z), g(Z))=0$ if and only if either $f(Z)$ or $g(Z)$ is a constant with probability 1 .
